(Dated: March 6, 2009)

We report a measurement of the differential cross section for the $\gamma n \rightarrow \pi^- p$ process from the CLAS detector at Jefferson Lab in Hall B for photon energies between 1.0 and 3.5 GeV and pion center-of-mass (c.m.) angles ($\theta_{c.m.}$) between 50° and 115°. We confirm a previous indication of a broad enhancement around a c.m. energy ($\sqrt{s}$) of 2.2 GeV at $\theta_{c.m.} = 90°$ in the scaled differential cross section, $s^7 \frac{d\sigma}{dt}$. Our data show the angular dependence of this enhancement as the scaling region is approached in the kinematic region from 70° to 105°.

PACS numbers: 13.60.Le, 24.85.+p, 25.10.+s, 25.20.-x

The $\gamma n \rightarrow \pi^- p$, $\gamma p \rightarrow \pi^+ n$ and $\gamma p \rightarrow \pi^0 p$ reactions are essential probes of the transition from meson-nucleon degrees of freedom to quark-gluon degrees of freedom in exclusive processes. The Constituent Counting Rule (CCR) [1, 2] was proposed as a signature for the search of such a transition. According to CCR, the differential cross section for high energy exclusive two-body reactions at a fixed c.m. angle scales as $d\sigma/dt \propto s^{-(n-2)}$. Here n is the total number of point-like particles and gauge fields in the initial plus final states and s and t are the invariant Mandelstam variables for the total energy squared and the four-momentum transfer squared, respectively. In the last decade or so, an all-orders demonstration of counting rules for hard exclusive processes has been shown arising from correspondence between the anti-de Sitter space and the conformal field theory [3], which connects superstring theory to QCD.

The differential cross section for many exclusive reactions [4, 5], at high energy and large momentum transfer, appears to obey the CCR, and in recent years, the scaling behavior has been observed also in deuteron photodisintegration [6, 7, 8, 9, 10] at a surprisingly low transverse momentum value above about 1.1 GeV/c [8, 10]. In addition to the early onset of scaling, some exclusive processes such as pp [11, 12] and πp [12, 13] elastic scattering, show a striking oscillation in the scaled differential cross section about the predicted quark counting rule behavior.

The CCR scaling behavior was studied in π^0 [14] and π^+ photoproduction from the proton [14, 15, 16], and in π^- for the first time in the Thomas Jefferson National Accelerator Facility (Jefferson Lab) Hall A experiment E94-104 [15, 16] using a deuterium target and an untagged bremsstrahlung photon beam. The data of the $\gamma n \rightarrow \pi^- p$ process exhibit an overall CCR scaling behavior at $\theta_{c.m.} = 70°$ and 90°, similar to what was observed in the π^+ channel at similar c.m. angles. The data [15] from both the $\gamma n \rightarrow \pi^- p$ and the $\gamma p \rightarrow \pi^+ n$ processes at $\theta_{c.m.} = 90°$ seem to hint at some oscillatory scaling behavior. Such oscillatory scaling behavior could be explained as suggested recently by Refs. [17, 18, 19]. The data also suggest that a transverse momentum of around 1.2 GeV/c might be the scale governing the onset of scaling, consistent with what has been observed in deuteron photodisintegration [8, 10]. One very interesting feature of the data is an apparent enhancement in the scaled differential cross section at $\theta_{c.m.} = 90°$ and at $\sqrt{s}$ range approximately from 1.8 GeV to 2.5 GeV. Furthermore, the scaled differential cross section drops by a factor of about 4 in a very narrow c.m. energy region (few hundreds of MeV) around 2.5 GeV.

The sudden drop in the scaled differential cross section may shed light on the transition between the aforementioned physical pictures. It is important to understand the nature of the enhancement followed by the dramatic drop in the scaled cross section and to test the onset of scaling behavior in pion photoproduction. This requires a detailed investigation of the pion photoproduction cross section in the $\sqrt{s}$ range from 1.8 to 2.5 GeV with very fine photon energy bins. (However, this energy range would not allow for a confirmation or refutation of the oscillatory scaling behavior hinted by experiment E94-104 [15].) In this paper, we report such a detailed study using high statistics data from the Jefferson Lab CEBAF Large Acceptance Spectrometer (CLAS) [20] in Hall B taken during the g10 running period [21].

The CLAS instrumentation was designed to provide large coverage of charged particles ($8° \leq \theta \leq 140°$). It is divided into six sectors by six superconducting coils which generate a toroidal magnetic field. Each sector acts as an independent detection system that includes drift chambers (DC), Cerenkov counters (CC), scintillation counters (SC) and electromagnetic calorimeters (EC). The drift chambers determine the trajectories of charged particles. With the magnetic field generated by the superconducting coils, the momenta of the charged particle can be determined from the curvature of the trajectories. The scintillation counters measure the time-of-flight and provide charged particle identification when combined with the momentum information from the drift chambers. Details about the CLAS can be found in Ref. [20].

A 24-cm long liquid-deuterium target was employed with the target cell positioned 25 cm upstream from the CLAS nominal center. A tagged-photon beam [22] generated by a 3.8-GeV electron beam incident on a gold radiator with a radiation length of 10^{-4}, corresponded to a maximum $\sqrt{s}$ of 2.8 GeV for the process of interest. The event trigger required at least two charged particles in different sectors. Two magnetic field settings were used during the experiment, corresponding to a low-field setting (with toroidal magnet current I=2250 A) for better forward angle coverage , and a high-field setting (I=3375 A) for better momentum resolution. About 10^{10} triggers were collected during the g10 running period of about two months.

The raw data collected from the experiment were first processed to calibrate and convert the information from the detector subsystems to physical variables for detected particles such as energy, momentum, position and timing information. The events of interest for which the photon coupled to the neutron inside the deuteron, were selected by ensuring a proton and a π^- in the final state. The difference of the reconstructed time of photon and charged particles at the reaction vertex was required to be within 1 ns to ensure that they came from the same accelerator electron bunch, which had a period of 2.004 ns. The momentum of the spectator proton in the deuteron is mostly below 200 MeV/c and is therefore not detected by CLAS. The 4-momentum of the undetected proton was reconstructed by energy-momentum conservation. Only events with missing mass around the proton mass were selected to make sure that the missing particle was the undetected proton. Shown in Fig. 1(a) is a typical reconstructed missing mass squared distribution. A 3σ cut was applied to identify the proton. Monte Carlo simulations for the $\gamma n \to \pi^- p$ process based on a phase space generator have been carried out to determine the acceptance. In the simulation, the neutron momentum distribution inside the deuteron is based on the deuteron wave function obtained from the Bonn potential [23]. Fig. 1(b) shows the reconstructed proton momentum from the experimental data and the simulation. The excellent agreement between the data and the Monte Carlo for a missing momentum below 200 MeV/c justified the cut we used (shown by the dashed line) in our analysis to select the quasifree events of $\gamma n \to \pi^- p$ from deuterons.

To extract the cross section, the aforementioned phase space based simulation is used to correct for events lost due to geometrical constraints and detector inefficiencies. The response of the CLAS detector was simulated in GEANT. More than 10^8 of events were generated and passed through the simulation. The simulated data were then processed to incorporate the subsystem efficiencies and resolutions extracted from the experiment. The DC wire efficiency and SC efficiency were studied in detail. The "excluded-layer method" [24] was used to study the DC wire efficiency and identify the bad DC regions. The SC efficiency was extracted by studying the SC occupancies. The correction due to the SC inefficiency is about 20% for the $\gamma n \to \pi^- p$ channel. All the simulated data were then processed by the same software used in the real data processing and analysis. The ratio between the events that passed the simulation and the generated events is a product of the detector efficiency and the acceptance.

The final state interaction (FSI) effects must be taken into account before one extracts cross sections on the neutron since a deuteron target is used. The FSI correction is estimated according to the Glauber formulation [25] and this correction is about 20%.

The differential cross section in the c.m. frame of the γn system is then given by

$$\frac{d\sigma}{d\Omega_{c.m.}} = \frac{N}{t_G \epsilon} \frac{1}{N_\gamma} \frac{A}{\rho L N_A} \frac{1}{d\Omega_{c.m.}}, \tag{1}$$

where t_G is the correction [25] for the FSI, ϵ is the product of the detector efficiency and acceptance, N is the number of events, N_γ is the total number of photons incident on the target, and A, N_A, L, ρ are deuteron atomic mass, Avogadro's number, target length and target density, respectively. The scaled differential cross section is defined as

$$s^7 \frac{d\sigma}{dt} = s^7 \frac{d\sigma}{d\Omega_{c.m.}} \frac{d\Omega_{c.m.}}{dt} = s^7 \frac{d\sigma}{d\Omega_{c.m.}} \frac{\pi}{E^{\gamma}_{c.m.} p^{\pi^-}_{c.m.}}, \tag{2}$$

where $E^{\gamma}_{c.m.}$ and $p^{\pi^-}_{c.m.}$ are the photon energy and π^- momentum in the c.m. frame, respectively. The results from the high magnetic field setting are consistent with those from the low magnetic field setting within systematic uncertainties.

There are three major sources of systematic uncertainties: the luminosity, the FSI correction, and the background. We studied the target thickness fluctuations as seen by the beam, as well as the run-dependent, and beam-current-dependent fluctuations of the normalized yield. All of them contribute to the uncertainty in the luminosity, and in total this uncertainty is less than 5%. The uncertainty of the Glauber calculation for the FSI correction was estimated to be 5% in Ref. [15]. To study the model uncertainty in calculating the FSI correction, we carried out another calculation using the approach of Ref. [26]. Both methods agree within 10%. A 10% systematic uncertainty to the differential cross section is assigned for the FSI correction. The background in the missing mass peak region is about 2% - 7% depending on the photon energy and an example is shown in Fig. 1 (left). According to Monte Carlo simulations, the background could come from the poorly reconstructed real events due to the DC resolution. Therefore, no background was subtracted in this analysis, instead the fitted background was assigned as the systematic uncertainty. The overall systematic uncertainty is between 11% to 13% on the extracted differential cross sections.

Fig. 2 shows the scaled differential cross section $s^7 \frac{d\sigma}{dt}$ as a function of $\sqrt{s}$ for $\theta_{c.m.} = 90^\circ$ for three different channels. The results from this experiment are shown in the middle panel as red solid circles with statistical uncertainties, and the systematic uncertainty is shown as a band. The error bars for E94-104 [15] include both the statistical and systematic uncertainties, while only statistical uncertainties are shown for the π^0 data [27] and the π^+ data [28]. All other world data are collected from

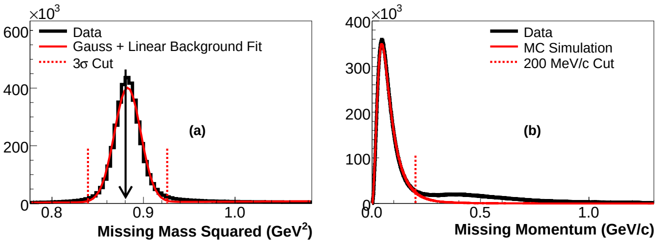

FIG. 1: (color online). (a): Reconstructed missing mass squared of the spectator proton fitted with a Gaussian plus linear function. The arrow indicates the mass squared of the proton; (b): Reconstructed spectator proton momentum (missing momentum) from this experiment together with a Monte Carlo simulation.

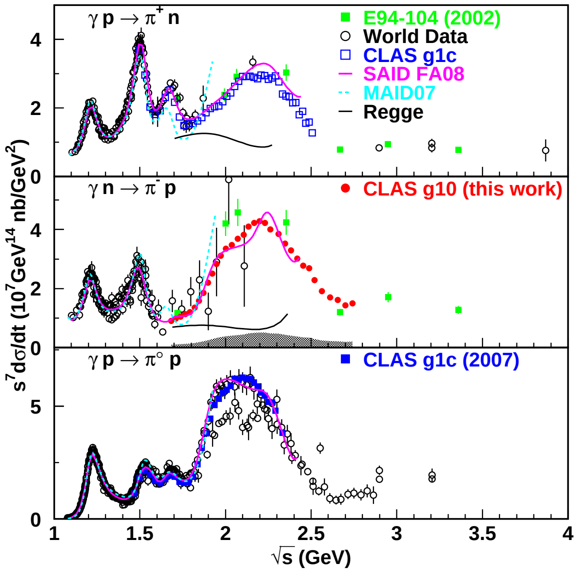

FIG. 2: (color online). Scaled differential cross section $s^7\frac{d\sigma}{dt}$ as a function of $\sqrt{s}$ for $\theta_{c.m.} = 90^\circ$ for three different channels. The upper panel is for the $\gamma p \rightarrow \pi^+ n$ process, the middle panel is for the $\gamma n \rightarrow \pi^- p$ process, and the lower panel is for the $\gamma p \rightarrow \pi^0 p$ process. The green solid squares are results from Ref. [15] and the results from this experiment are shown as red solid circles. Results from Dugger *et al.* [27] on neutral pion production are shown as blue solid squares. The blue open squares are recent CLAS data on π^+ production [28]. The SAID FA08 results [28] are shown as the magenta curves in all three panels. The prediction from a Regge approach [32] is shown in the top and middle panels by black curves. The black open circles are the world data collected from Refs. [4, 29].

Refs. [4, 29]. There are three distinct features shown in the data: a broad enhancement around $\sqrt{s}$ of 2.1 GeV; a marked fall-off of the differential cross section in a narrow energy window of about 300 MeV above this enhancement; and the suggested [15] onset of the CCR scaling for $\sqrt{s}$ around 2.8 GeV. The second feature was suggested by Jefferson Lab experiment E94-104 [15] (shown as green solid squares) and the $\pi^- p$ total scattering cross section data [30]. The drastic fall-off of the cross section has now been firmly established by the results from this experiment. Also shown are the results of the SAID FA08 partial wave analysis [28] (magenta), the MAID07 model [31] (blue), and the prediction from a Regge approach [32] (black).

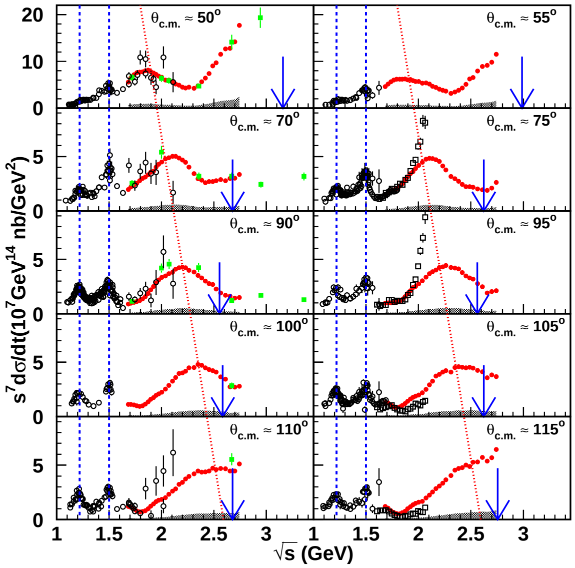

FIG. 3: (color online). Scaled differential cross section $s^7\frac{d\sigma}{dt}$ as a function of $\sqrt{s}$ for $\theta_{c.m.} = 50^\circ$ to 115°. The arrows indicate the location of $\sqrt{s}$ corresponding to a transverse momentum value of 1.1 GeV/c. The green solid squares are results from Ref. [15]. The results from this experiment are shown as red solid circles. The black open circles and open squares are the world data collected from Refs. [4, 29] and [33], respectively. Errors on the data from CLAS are the quadratic sums of the statistical and systematic uncertainties. The blue dashed lines indicate the known resonances, and the red dotted lines illustrate the angular dependent feature of the broad enhancement structure discussed in the text.

The Regge approach does not describe our data and the deviation is speculated to be due to baryon resonances [32]. While the SAID FA08 fit has been greatly improved by the CLAS π^0 [27] and the π^+ data [28], it does not give as good a description of the data near the peak of the enhancement. Further, it lacks the constraint on the π^- channel and does not describe our data well above 2.4 GeV in $\sqrt{s}$. The precision data presented here will help to further constrain the SAID fit and will allow for a determination of the corresponding neutron electromagnetic parameters for 4-star PDG resonances. These studies will be reported in a future publication.

Fig. 3 shows the scaled differential cross section $s^7\frac{d\sigma}{dt}$ as a function of $\sqrt{s}$ for $\theta_{c.m.} = 50^\circ$ to 115° with an angular bin size of 5° for the $\gamma n \to \pi^- p$ process. As in Fig. 2, the systematic uncertainties are shown as bands in Fig. 3. The blue arrows indicate the location of $\sqrt{s}$ corresponding to a pion transverse momentum (p_T) of 1.1 GeV/c. This p_T value was suggested to govern the scaling onset by Refs. [8, 10]. We note the large discrepancy between our results and those from Ref. [33] at $\theta_{c.m.} = 75°$ and 95°. We also note that the SAID fits [27, 28] did not include data from Ref. [33]. An angular-dependent feature in the scaled differential cross section is clearly seen in our data. The aforementioned broad enhancement around a $\sqrt{s}$ value of 2.1 GeV at $\theta_{c.m.} = 90°$ seems to shift as a function of $\theta_{c.m.}$ from $\sqrt{s}$ of 1.80 GeV at 50° to 2.45 GeV at 105° as shown by the red dotted lines. Our studies show that such behavior is not an artifact of the s^7 scaling factor. It is not clear whether this enhancement dies off for $\theta_{c.m.} > 105°$ or whether it shifts to further higher energies. The blue dotted lines indicate the locations of the nucleon resonances around 1.2 GeV and 1.5 GeV which, as expected, do not change with $\theta_{c.m.}$. However, such an angular dependent scaling behavior is not present in the π^+ and π^0 channels from the proton [34]. Our preliminary studies show that such a behavior is not due to the FSI correction, while more complete calculations are in progress.

The approach to the scaling region is seen in Fig. 3 at the highest p_T kinematics, from $\theta_{c.m.} = 70°$ to 105°. In the forward angle kinematics of 50°, higher energies are necessary to reach a p_T value of 1.1 GeV/c, suggested by the deuteron photodisintegration data [8, 10] as the value for the onset of the scaling behavior. It is very important to extend this experiment to much higher photon energies, such as is feasible at 6 GeV at Jefferson Lab currently and at 11 GeV at the energy-upgraded Jefferson Lab facility in the future, and to carry out similar measurements on the $\gamma p \to \pi^+ n$ and the $\gamma p \to \pi^0 p$ processes, and polarization measurements for all three channels. Such studies will be essential in understanding the nature of the observed enhancement, the running behavior of the enhancement structure in the π^- channel, and to understand where and how the transition from the nucleon-meson to the quark-gluon degrees of QCD takes place.

We acknowledge the outstanding efforts of the staff of the Accelerator and Physics Divisions at Jefferson Lab who made this experiment possible. This work was supported in part by the U.S. Department of Energy, the National Science Foundation, the Italian Istituto Nazionale di Fisica Nucleare, the French Centre National de la Recherche Scientifique and Commissariat à l'Energie Atomique, and the Korea Science and Engineering Foundation. Jefferson Science Associates (JSA) operates the Thomas Jefferson National Accelerator Facility for the U.S. Department of Energy under contract DE-AC05-060R23177.

[34] When the π^+ data (Refs. [4, 29, 33]) and π^0 (Dugger *et al.* [27]) are plotted in the same way as the π^- data in Fig. 3, the angular-dependent behavior seen in the $\gamma n \to \pi^- p$ process is not present.
